Adiponectin, a recently discovered adipocyte-derived peptide, is involved in the regulation of insulin sensitivity and lipid oxidation and, purportedly, in the development of atherosclerosis and coronary heart disease in humans. 

Objective To assess prospectively whether plasma adiponectin concentrations are associated with risk of myocardial infarction (MI).

Design, Setting, and Participants Nested case-control study among 18,225 male participants of the Health Professionals Follow-up Study aged 40 to 75 years who were free of diagnosed cardiovascular disease at the time of blood draw (1993-1995). During 6 years of follow-up through January 31, 2000, 266 men subsequently developed nonfatal MI or fatal coronary heart disease. Using risk set sampling, controls were selected in a 2:1 ratio matched for age, date of blood draw, and smoking status (n = 532).

Main Outcome Measure Incidence of nonfatal MI and fatal coronary heart disease by adiponectin level.

Results After adjustment for matched variables, participants in the highest compared with the lowest quintile of adiponectin levels had a significantly decreased risk of Mi (relative risk [RR], 0.39; 95% confidence interval [CI], 0.23-0.64; P for trend <.001). Additional adjustment for family history of MI, body mass index, alcohol consumption, physical activity, and history of diabetes and hypertension did not substantially affect this relationship (RR, 0.41; 95% CI, 0.24-0.70; P for trend <.001). Further adjustment for hemoglobin A1c or C-reactive protein levels also had little impact, but additional adjustment for low- and high-density lipoprotein cholesterol levels modestly attenuated this association (RR, 0.56; 95% CI, 0.32-0.99; P for trend = .02).

Conclusions High plasma adiponectin concentrations are associated with lower risk of MI in men. This relationship can be partly explained by differences in blood lipids and is independent of inflammation and glycemic status.

administered questionnaire and diet every 4 years by a self-administered food frequency questionnaire.\textsuperscript{24} Between 1993 and 1995, a blood sample was requested from all participants and returned by 18,225 participants. Men who provided samples were somewhat younger but were otherwise similar to those who did not provide samples. Based on this sample and after exclusion of participants with a history of cardiovascular disease prior to 1994, we identified 266 participants with incident nonfatal MI or fatal CHD between date of blood draw and return of the 2000 questionnaire (January 2000). Controls were randomly selected from participants with a blood sample and without history of cardiovascular disease at the time of case ascertainment in a 2:1 ratio and matched for age, date of blood draw, and smoking status (risk set sampling).\textsuperscript{25} Our analysis includes 1 participant who was selected as a control and subsequently had an event during follow-up. No control was selected twice in our analysis during the random selection process.

All participants gave written informed consent, and the Harvard School of Public Health Human Subjects Committee Review Board approved the study protocol.

Assessment of Nonfatal MI and Fatal CHD

Study physicians blinded to participants’ exposure status reviewed the medical records of all participants for whom nonfatal MI or fatal CHD was ever reported. Each questionnaire that is mailed biennially to participants of the HPFS contains a question on whether the participant has had “professional diagnosis . . . myocardial infarction (heart attack)” in the preceding 2 years. Myocardial infarction was confirmed if it met the World Health Organization’s criteria (symptoms plus either diagnostic electrocardiographic changes or elevated levels of cardiac enzymes).\textsuperscript{26} In about 70% of participants with reported MI, the diagnosis was confirmed using these methods. Reasons for nonconfirmation were either that no further information was available (because the participant or hospital did not consent to send the hospital records) or that a reported case was rejected. Nonconfirmed participants were excluded from the selection process. Deaths were identified from state vital statistics records and the National Death Index or reported by next of kin or the postal system. Fatal CHD was considered to have occurred if there was fatal MI confirmed by hospital records or on autopsy or if CHD was listed as the cause of death on the death certificate, if it was the underlying and most plausible cause, and if evidence of previous CHD was available. In our analysis, 196 participants had nonfatal MI and 70 had fatal CHD as the qualifying event.

Assessment of Medical History, Anthropometric Data, and Diet and Lifestyle Factors

Anthropometric data, lifestyle factors, and diet were derived from the 1994 questionnaire. Body mass index was calculated as weight in kilograms divided by the square of height in meters. Nutrient intake was computed based on a semiquantitative food frequency questionnaire (which inquires about average food intake during the past year) using composition values from the US Department of Agriculture sources,\textsuperscript{27} supplemented with other data. Physical activity was expressed as metabolic equivalent task (MET)–hours based on self-reported types and durations of activities over the previous year.\textsuperscript{28} One MET-hour is equivalent to energy expenditure while sitting quietly for 1 hour. Medical history was derived from the questionnaires between 1986 and 1994. The questionnaires and the validity and reproducibility of the collected data and measurements have been reported in detail elsewhere.\textsuperscript{24,29-33}

Measurement of Biochemical Variables

Blood samples were collected in three 10-mL liquid EDTA blood tubes, placed on ice packs, stored in Styrofoam containers, and returned to our laboratory via overnight courier, with more than 95% arriving within 24 hours. After arrival, blood samples were centrifuged and aliquoted for storage in the vapor phase of liquid nitrogen freezers (−130°C or colder). Fewer than 15% of the samples were slightly hemolyzed and very few were moderately hemolyzed (<3%), lipemic (<1%), or not cooled on arrival (<0.5%).

Plasma adiponectin concentrations were measured by competitive radioimmunoassay (Linco Research Inc, St Charles, Mo) with a coefficient of variation of 3.4% (n=39). In a previous analysis, adiponectin levels had excellent intraclass correlation coefficients measured in participants over a period of 1 year and were not substantially affected by transport conditions.\textsuperscript{34}

Total cholesterol was measured enzymatically\textsuperscript{35}, LDL cholesterol by a homogeneous direct method from Genzyme Corp, Cambridge, Mass; HDL cholesterol using a direct enzymatic colorimetric assay\textsuperscript{37}, and triglycerides enzymatically with correction for endogenous glycerol.\textsuperscript{38} The assays used for lipoprotein and lipid analysis are approved by the US Food and Drug Administration for clinical use, and coefficients of variation were less than 6%. Hemoglobin A\textsubscript{1c} (HbA\textsubscript{1c}) was measured by turbidimetric immunoinhibition, and C-reactive protein (CRP) concentrations were determined using an immunoturbidimetric high-sensitivity assay on a Hitachi 911 analyzer (Roche Diagnostics, Indianapolis, Ind) and reagents and calibrators from Denka Seiken (Niigata, Japan). The laboratory used (N.R.) is certified by the Centers for Disease Control and Prevention/National Heart, Lung, and Blood Institute Lipid Standardization Program.

Sixty-five percent of the participants in the present analysis provided fasting blood samples (≥8 hours since last meal; 67% among cases and 64% among controls) (P=.36). Data on LDL cholesterol and CRP levels were each missing in 1 participant; these values were replaced by the median concentrations in this cohort.
ADIPONECTIN LEVELS AND RISK OF MI IN MEN

Statistical Analyses
Continuous variables are presented as means and standard deviations or medians and interquartile ranges and were compared between cases and controls using the unpaired t test or the Wilcoxon unpaired rank sum test. Proportions were compared using the χ² test. Associations between adiponectin levels and selected cardiovascular risk factors were examined in cases and controls using an age-adjusted Spearman partial correlation coefficient.

Adiponectin levels were categorized into quintiles based on control participants. Unconditional logistic regression adjusted for matched variables (age <50, 50-54, 55-59, 60-64, or ≥65 years; smoking status never, past, or current; and month of blood draw in 5 categories) was used to investigate the association between baseline adiponectin concentrations and incidence of nonfatal MI or fatal CHD (events). To test for linear trend across categories, we used log-transformed adiponectin levels. In our multivariable model, we further adjusted for family history of MI before age 60 years (yes/no), alcohol intake (nondrinker; 0.1-4.9, 5.0-14.9, 15.0-29.9, or ≥30.0 g/d; or missing), body mass index (<20, 20-24, 25-29, 30-34, or ≥35), physical activity (quintiles), and history of diabetes (yes/no) and hypertension (yes/no) at baseline. We repeated our main analysis using conditional logistic regression and found essentially the same results. Because of the design of our study, the odds ratio derived from logistic regression directly estimates the incidence rate (hazard) ratio and, therefore, the relative risk (RR).25,39

We next examined the impact of potential intermediate markers by sequentially adding LDL and HDL cholesterol and log-transformed triglyceride, HbA₁c, and CRP levels as continuous variables to our models, and estimated the multivariable-adjusted RR associated with an increase of (continuous) log-transformed adiponectin levels by 2 units on a log scale, which corresponds to a doubling in adiponectin levels on the original scale.

For stratified analysis, we also calculated the multivariable-adjusted RR associated with a doubling in adiponectin levels. We defined the metabolic syndrome similarly as recently proposed by the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults40 as having 3 or more of the following 5 abnormalities: body mass index of at least 25; triglyceride levels of at least 150 mg/dL (0.82 mmol/L); HDL cholesterol levels of less than 40 mg/dL (1.04 mmol/L); history of hypertension; and history of diabetes.

RESULTS
Characteristics and biomarker levels of cases and controls are presented in TABLE 1. Cases had a nonsignificantly higher body mass index and were more likely to have a history of hypertension and diabetes and a family history of MI before age 60 years, although the latter did not reach statistical significance. Cases consumed slightly less alcohol and were less physically active than controls, although these differences were not statistically significant. Cases had significantly lower mean adiponectin levels than controls (15.6 [SD, 8.5] mg/L vs 17.9 [SD, 8.8] mg/L; P < .001) and, as expected, significantly higher levels of total and LDL cholesterol, triglycerides, and HbA₁c and lower HDL cholesterol levels.

We next examined the association of adiponectin levels with selected cardiovascular risk factors among cases and controls (TABLE 2). After adjustment for age, adiponectin was significantly positively correlated with HDL cholesterol and physical activity and negatively correlated with triglyceride, CRP, and HbA₁c levels and body mass index. Results were similar when cases and controls were combined in this analysis.

TABLE 3 shows the estimated RRs of MI during 6 years of follow-up across quintiles of adiponectin levels at baseline. After adjustment for matched variables, participants in the highest compared with the lowest quintile of adiponectin levels had a significantly decreased risk of MI (RR, 0.39; 95% confidence interval [CI], 0.23-0.64; P for trend on a log scale <.001). Further adjustment for family history of MI, body mass index, alcohol consumption, physical activity, and history of diabetes and hypertension at baseline did not substantively affect this relationship (RR, 0.41; 95% CI, 0.24-0.70; P for log trend <.001), whereas additional adjustment for LDL and HDL cholesterol levels modestly attenuated the association (RR, 0.56; 95% CI, 0.32-0.99; P for log trend = .02).

We next examined the impact of potential intermediary biomarkers on the relation between adiponectin and risk of MI, by sequentially adding these markers as continuous variables to our model, and calculated the multivariable-adjusted RR associated with an increase of (continuous) log-transformed adiponectin levels by 2 units on
In this nested case-control study, we found high plasma adiponectin levels associated with lower risk of MI over a follow-up period of 6 years among men without previous cardiovascular disease. This association was independent of traditional cardiovascular risk factors that might be associated with adiponectin levels and, thus, are potential confounders.

a log scale, which represents a doubling in adiponectin concentrations on the original scale; however, as can be seen from the FIGURE, after adjustment for LDL and HDL cholesterol, which modestly attenuated the association, addition of triglycerides, HbA1c, and CRP levels did not substantively affect the results.

Table 4 shows the multivariable- and lipid-adjusted relative risk of MI associated with a doubling in adiponectin levels in subgroups of our population. In general, the results were similar among younger and older participants and in different strata of cardiovascular risk factors. Because our subset included only a limited number of participants with diabetes at baseline, we were not able to calculate effect estimates within this subgroup; however, exclusion of these participants did not substantively alter the results as presented in Table 4. Similarly, exclusion of participants with a parental history of MI before age 60 years did not affect the results. Results were also similar in different strata of alcohol consumption and physical activity and among those taking and not taking aspirin.

We repeated our main analysis excluding participants who developed the qualifying event during the first 2 years of follow-up and found essentially the same results (RR associated with a doubling in adiponectin levels, 0.77; 95% CI, 0.61-0.97; P = .02). Similarly, we found the same results when we excluded nonfasting participants from our main analysis (RR, 0.80; 95% CI, 0.61-1.06; P = .11) and when we excluded current smokers (RR, 0.83; 95% CI, 0.67-1.04; P = .11). When we stratified our analysis by type of event, we found an inverse association between adiponectin and risk of nonfatal MI (RR, 0.73; 95% CI, 0.58-0.93; P = .009) but not risk of fatal CHD (RR, 0.97; 95% CI, 0.67-1.41; P = .88); however, the latter group included only 70 cases.

### COMMENT

In this nested case-control study, we found high plasma adiponectin levels associated with lower risk of MI over a fol-
confounders. Of note, the relationship was also independent of hypertension, diabetes, and HbA1c levels, factors that were closely related to adiponectin levels in previous studies. Furthermore, the relationship was only partly explained by differences in blood lipid levels and was independent of CRP.

Our results are in line with previous cross-sectional studies of adiponectin levels and coronary artery disease.5,43,44 Ku- mada et al45 reported significantly lower adiponectin levels in 225 consecutive male patients aged 40 to 69 years with coronary artery disease compared with 225 voluntary blood donors and a 2.05-fold increased risk of coronary artery disease (95% CI, 1.29-4.95) comparing participants in the lowest and highest quartiles of adiponectin levels. After adjustment for diabetes, dyslipidemia, hypertension, smoking, and body mass index. In a study by Hotta et al,7 adiponectin levels were lowest in participants with coronary artery disease and type 2 diabetes, intermediate in those without diabetes, and highest in non-diabetic individuals. These significant differences persisted after adjustment for other cardiovascular risk factors. Ko- jima et al46 found significantly lower adiponectin levels in 34 participants with acute MI compared with 35 individuals without significant coronary artery stenosis who were matched for age, sex, and body mass index.

Among 227 hemodialysis patients, Zoccali et al47 found in a prospective setting that after adjustment for cardiovascular risk factors, adiponectin was inversely related to cardiovascular events (hazard ratio, 0.97; 95% CI, 0.93-0.99 for an increase in adiponectin levels of 1 mg/L) over a mean follow-up of 2.5 years, although adiponectin levels did not predict overall mortality. A study by Lindsay et al48 found no significant association between plasma adiponectin levels and risk of CHD in a nested case-control study among 372 American Indians after adjustment for other cardiovascular risk factors (odds ratio for 1-SD change in adiponectin, 0.90; P = .34) however, in stratified analyses, they found a significantly reduced risk among those with type 2 diabetes (comprising about 61% of their initial data set; odds ratio, 0.40; P = .02). As an extension to these reports, our study is among the first to suggest that

¶Lipids include low- and high-density lipoprotein cholesterol.
plasma adiponectin levels may predict cardiovascular events years in advance in a population without diagnosed cardiovascular disease. In fact, several lines of evidence suggest that adiponectin may be not only a marker of cardiovascular risk but also a causal risk factor. First, adiponectin may lower the risk of cardiovascular disease by improving insulin sensitivity and blood lipid levels, as suggested by animal and human data. Adiponectin has been shown to result in activation of the adenosine monophosphate–activated protein kinase in skeletal muscle and liver, leading to phosphorylation of acetyl coenzyme A carboxylase, increased fatty acid oxidation and glucose uptake, reduced fatty acid synthesis, and reduction of molecules involved in gluconeogenesis. Downstream effects may include reduced triglyceride content in liver and skeletal muscle and suppression of hepatic glucose production. This may also explain the finding in our study and in previous studies that adiponectin is inversely associated with triglyceride levels and positively associated with HDL cholesterol levels.

Second, adiponectin may lower CRP and other inflammatory cardiovascular risk factors. Thus, injection of an adiponectin-producing adenovirus was shown to decrease the significantly increased adipose tissue tumor necrosis factor α (TNF-α) messenger RNA and plasma TNF-α levels in adiponectin knockout mice. In line with these animal experiments, human studies found inverse associations between adiponectin and the inflammatory markers TNF-α, interleukin 6, and CRP. Third, adiponectin may modulate the vascular response to lipid and inflammatory stimuli. Thus, adiponectin inhibits endothelial nuclear transcription factor NF-κB signaling, which mediates the effects of TNF-α and other cytokines.

Furthermore, adiponectin suppresses lipid accumulation and class A scavenger receptor expression in macrophages and, consequently, the transformation of macrophages to foam cells, which plays an important role in the atherogenic process. It was shown that adiponectin binds to subendothelial collagen and suppresses proliferation and migration of human aortic smooth muscle cells. In apo-lipoprotein E-deficient mice, adiponectin significantly reduced the development of atherosclerosis that usually occurs in these animals. Consistent with these animal studies, low adiponectin levels were found in participants with coronary artery disease.

Our study has some limitations. The inverse relationship between plasma adiponectin levels and risk of MI was not linear but, rather, plateaued in the middle quintiles and was most pronounced in the highest quintile; however, we used rather conservative methods to estimate the RRs, which makes it unlikely that our results are driven by outliers.

Abbreviations: BMI, body mass index (expressed as weight in kilograms divided by the square of height in meters); CI, confidence interval; CRP, C-reactive protein; HDL, high-density lipoprotein; LDL, low-density lipoprotein; RR, relative risk; SI conversions: To convert HDL and LDL cholesterol to mmol/L, multiply by 0.0259. To convert triglycerides to mmol/L, multiply by 0.0113.

*Effect estimates and P values were calculated using log-transformed adiponectin level as a continuous variable, adjusted for matched variables (age, smoking status, and month of blood draw), body mass index, family history of myocardial infarction, history of diabetes, history of hypertension, alcohol intake, physical activity, and LDL and HDL cholesterol levels.

†Indicates the median of the corresponding value for controls.

§Not adjusted for the stratification variable.

Moderate drinkers includes participants who drank 0.1-29.9 g/d of alcohol. Heavy drinkers (≥30 g/d) were excluded from this subgroup analysis.
Furthermore, this type of nonlinear relationship is consistent with other reports on adiponectin and risk of CHD and type 2 diabetes. A single assessment of adiponectin may be susceptible to short-term variation, which would bias the results toward the null. However, in a previous analysis, we found intradi-
vidual adiponectin levels to be reasonably stable over time, with an intraclass correlation coefficient of 0.85 for adiponectin levels measured within participants 1 year apart. It is currently unknown whether long-term storage of blood samples affects plasma adiponectin levels; however, if anything, this would tend to increase measurement error and, thus, bias the results toward the null. Because the ranges of anthropometric parameters in the present study were quite broad, the biological relationships found should be generalizable. Future studies should address whether our findings also apply to women and individuals with different racial/ethnic origins and socioeconomic status and whether adiponectin levels predict cardiovascular events beyond a follow-up period of 6 years. It is possible that the observed association is confounded by a yet-to-be-determined factor; however, we adjusted our analysis for established and novel cardiovascular risk factors. Furthermore, although the results failed to reach formal statistical significance in certain subgroups, possibly because of limited sample size, we found comparable and robust risk reductions in various low and high cardiovascular risk groups. While we excluded participants with diagnosed cardiovascular disease at baseline, we cannot exclude the possibility that participants had undiagnosed atherosclerosis. However, we found similar results when we excluded participants who developed MI during the first 2 years of follow-up. Not all participants in our data set provided fasting blood samples, which could affect the measurement of triglyceride levels; however, any potential misclassification should be nondifferential. Furthermore, results were similar when we restricted our analysis to fasting participants. Finally, LDL cholesterol levels in our study were measured directly, without using the Friedewald formula, and, thus, do not depend on fasting status. We used body mass index instead of waist-hip ratio to assess abdominal obesity, which may lead to misclassification of the metabolic syndrome; however, the distribution of metabolic abnormalities was similar to that recently reported for the general population, and the metabolic syndrome was used for secondary analyses only. Since plasma insulin levels were not available in our data set, we were unable to examine the impact of this potentially intermediary variable; however, adjustment for HbA1c, as a marker of glycemic control did not appreciably change the results. It should be noted that some of the variables that we adjusted for may be causal mediators instead of confounders, which would underestimate the true relationship between adiponectin levels and risk of MI.

In conclusion, we found that high plasma adiponectin levels are associated with a lower risk of MI over a follow-up period of 6 years among men without previous cardiovascular disease, independent of traditional cardiovascular disease risk factors. Particularly, this relationship can only partly be explained by differences in blood lipids and is independent of inflammation and glycemic status at baseline. The effect of adiponectin on risk of CHD merits further study.

Author Contributions: Dr Pischon had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study concept and design: Pischon, Girman, Hotamisligil, Rimm.

Acquisition of data: Rimm.

Analysis and interpretation of data: Pischon, Girman, Hotamisligil, Rifai, Hu, Rimm.

Drafting of the manuscript: Pischon, Girman.

Critical revision of the manuscript for important intellectual content: Pischon, Girman, Hotamisligil, Rifai, Hu, Rimm.

Statistical expertise: Pischon, Girman, Hu.

Obtained funding: Girman, Rimm.

Administrative, technical, or material support: Girman, Rimm.

Supervision: Hotamisligil, Rimm.

Funding/Support: This study was supported by Na-
tional Institutes of Health (NIH) grants HL53464, CA50075, and AA11181 and additional funding from a research grant from Merck & Co Inc, West Point, Pa. Dr Pischon is a Jetson Lincoln fellow, supported in part by an unrestricted gift from Mr Lincoln.

Role of the Sponsors: In addition to the funding and general oversight of all NIH grants by the respective agencies, Merck Research Laboratories also provided additional funding for several years beyond the initial proposal. Harvard University investigators had sole responsibility for the design and conduct of the study and collection, preparation, and analysis of the data. As a research author, Dr Girman, an employee of Merck, had intellectual input into the preparation of the manuscript, although the final approval of the manuscript remained the responsibility of the Harvard University investigators, who allowed Merck access to the data. Drs Hotamisligil and Stampfer are also Merck employees.

Acknowledgment: We thank Mei Stampfer, MD, DrPH, for his advice on this study and Ellis O’Reilly for programming review.
