**Familial Hypercholesterolemia** is the paradigm of the established relationship between increased low-density lipoprotein cholesterol (LDL-C) and cardiovascular disease. This monogenic disorder is characterized by exposure to severely elevated LDL-C levels from birth onward. Endothelial function, measured as flow-mediated dilatation of the brachial artery, is already impaired in prepubertal children with familial hypercholesterolemia. In addition to these early functional changes, accumulation of LDL-C in children with familial hypercholesterolemia leads to deterioration of the vascular morphology and gives rise to increased intima-media thickness (IMT) of the carotid arteries. As a sequel to these observations, myocardial ischemia and coronary artery stenoses have been documented in young adults with this disorder. The sequence of events in untreated children proceeds from endothelial dysfunction to increased atherosclerotic disease they develop later in life. Although intervention therapy in the causal pathway of this disorder has been available for more than a decade, the long-term efficacy and safety of cholesterol-lowering medication have not been evaluated in children.

**Objective** To determine the 2-year efficacy and safety of pravastatin therapy in children with familial hypercholesterolemia.

**Design** Randomized, double-blind, placebo-controlled trial that recruited children between December 7, 1997, and October 4, 1999, and followed them up for 2 years.

**Setting and Participants** Two hundred fourteen children with familial hypercholesterolemia, aged 8 to 18 years and recruited from an academic medical referral center in the Netherlands.

**Intervention** After initiation of a fat-restricted diet and encouragement of regular physical activity, children were randomly assigned to receive treatment with pravastatin, 20 to 40 mg/d (n = 106), or a placebo tablet (n = 108).

**Main Outcome Measures** The primary efficacy outcome was the change from baseline in mean carotid IMT compared between the 2 groups over 2 years; the principal safety outcomes were growth, maturation, and hormone level measurements over 2 years as well as changes in muscle and liver enzyme levels.

**Results** Compared with baseline, carotid IMT showed a trend toward regression with pravastatin (mean [SD], −0.010 [0.048] mm; P = .049), whereas a trend toward progression was observed in the placebo group (mean [SD], +0.005 [0.044] mm; P = .28). The mean (SD) change in IMT compared between the 2 groups (0.014 [0.046] mm) was significant (P = .02). Also, pravastatin significantly reduced mean low-density lipoprotein cholesterol levels compared with placebo (−24.1% vs +0.3%, respectively; P < .001). No differences were observed for growth, muscle or liver enzymes, endocrine function parameters, Tanner staging scores, onset of menses, or testicular volume between the 2 groups.

**Conclusion** Two years of pravastatin therapy induced a significant regression of carotid atherosclerosis in children with familial hypercholesterolemia, with no adverse effects on growth, sexual maturation, hormone levels, or liver or muscle tissue.

For editorial comment see p 377.
We therefore performed a placebo-controlled, randomized clinical trial with pravastatin in 8- to 18-year-old children with familial hypercholesterolemia; we used carotid IMT to measure efficacy and growth and maturation to assess the safety of long-term exposure. Carotid IMT represents the combined intima and media thickness of the arterial wall, and numerous studies have shown that this surrogate marker of atherosclerotic vessel wall change is sensitive to risk intervention and constitutes a reliable indicator of clinical outcomes.17-19

METHODS
Study Design and Participants

The study was a prospective, randomized, double-blind, placebo-controlled trial in children with heterozygous familial hypercholesterolemia (Figure 1). The study recruited children between December 7, 1997, and October 4, 1999, at the Academic Medical Center, University of Amsterdam, the Netherlands, and followed them up for 2 years; the last patient left the study on November 4, 2001. Children were eligible when they met the following criteria: 1 parent with a definite clinical or molecular diagnosis of familial hypercholesterolemia; age between 8 and 18 years; after 3 months on fat-restricted diet, 2 fasting samples with LDL-C levels of at least 155 mg/dL (4.0 mmol/L) (99.6% chance of having an LDL receptor mutation20) and triglyceride levels below 350 mg/dL (4.0 mmol/L); adequate contraception use in sexually active girls; and no drug treatment for familial hypercholesterolemia or use of plant sterols. Reasons for exclusion were homozygous familial hypercholesterolemia, hypothyroidism, and abnormal levels of muscle or liver enzymes. The institutional review board at the Academic Medical Center approved the study protocol. Written informed consent was obtained from all children and their parents.

All children were instructed to continue a fat-restricted diet and to maintain habitual physical activity during the trial. Seven-day diet histories were obtained 18 months into the treatment period. Completed menu checklists were analyzed by a dietitian and compared with Dutch advice standards for children and adolescents21 and a survey of Dutch children’s and adolescents’ habits.22

Consenting children with familial hypercholesterolemia were randomly assigned to receive either pravastatin or placebo. Randomization was achieved by a computer-generated sequence in blocks of 8 participants. Children younger than 14 years of age received half a tablet (equivalent to pravastatin, 20 mg, in the intervention group), whereas those aged 14 years or older received 1 tablet (pravastatin, 40 mg) daily in the evening. Placebo tablets resembled pravastatin. Study drug compliance was monitored by tablet counting. Children were evaluated every 6 months for 2 years by a single physician masked to group assignment.

Primary Efficacy Outcome

The primary efficacy outcome of this study was defined as the change from baseline in mean carotid IMT compared between the pravastatin and placebo groups at 2 years of follow-up. Mean carotid IMT was defined as the mean IMT of the right and left common carotid, the carotid bulb, and the internal carotid far wall segments. For a given segment, IMT was defined as the average of the right and left IMT measurements. If on either side a segment was missing, IMT was defined as the value of the remaining segment: if both left- and right-side values were unavailable, the IMT value was considered missing for that segment, and in that situation, the mean carotid IMT was also considered missing.

One experienced sonographer (blinded) performed all B-mode ultrasound examinations. B-mode ultrasound image acquisition for the IMT measurements was performed at entry and after 1 and 2 years of follow-up. An Acuson 128XP/10v (Acuson Corp, Mountain View, Calif) ultrasound instrument equipped with a 5-10 MHz L7 (Acuson L7) and Extended Frequency ultrasound system software,
version 7.02 (Acuson Corp) was used. The left and right far walls of the carotid artery segments were imaged in a standardized magnification (2 × 2 cm). The sonographer saved a video still image of each segment as a 4:1 compressed JPEG file (Sony DCR-700P video still image recorder). At the end of the study, 1 image analyst (blinded) batch-read all ultrasound images in a random fashion regarding both participants and the order of their ultrasound visits. In-house–designed software (eTrack, version 2.3, W. J. Stok, Department of Physiology, Academic Medical Center, University of Amsterdam) was used as previously published.23

Lipids and Lipoproteins
Blood samples for measurement of lipids and lipoproteins were collected after at least a 12-hour overnight fast at baseline, 3-month intervals for the first year, and 6-month intervals the second year. Plasma total cholesterol, high-density lipoprotein cholesterol, and triglyceride levels were determined with the use of commercially available kits (Boehringer, Mannheim, Germany). Levels of LDL-C were calculated using the Friedewald equation.24 Lipoprotein(a) concentrations were determined with the use of the Apo-Tek enzyme-linked immunosorbent assay (Organon Teknika, Durham, NC). Mutations in the LDL receptor gene were detected as previously described.25

Primary Safety Outcome
To measure deleterious effects on maturation and/or growth, we measured the levels of sex steroids, gonadotropins, and variables of the pituitary-adrenal axis at baseline and at 1 and 2 years. Measurements of children’s height, weight, body surface area,26 Tanner staging (genitals/breasts, pubic and axillary hair), and menarche or testicular volume were also obtained at the same time points. Body mass index was calculated as weight in kilograms divided by the square of height in meters. School records were reviewed for education level and yearly progress. To detect potential adverse effects on muscle and liver enzymes, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and creatine phosphokinase (CPK) were assessed at the same time as lipids.

Sample Size Calculation
Primary Efficacy Outcome. The sample size for this study was based on the primary efficacy outcome, change from baseline to 2-year follow-up in mean carotid IMT compared between the 2 groups. Prior to the trial, replicate ultrasound measurements were performed in 20 children with familial hypercholesterolemia and 20 unaffected siblings. The standard deviation (σ) of the means of the differences of the paired, repeated combined carotid IMT measurements was 0.045 mm (the σ of the mean for children with familial hypercholesterolemia and that of their siblings were similar). A sample size, N, for an effect size, Δ, and the σ were calculated according to N = 2[(Zα + Zβ) / σΔ]². We set the 2-sided α (type I error) at .05 and the β (type II error) at .10 (power of 90%). Based on these assumptions, a sample size of approximately 100 children in each group was needed to detect a difference of 0.02 mm in mean carotid IMT over a 2-year period.

Primary Safety Outcome. We subsequently used this sample size to calculate which safety outcome differences could be detected. Height measurements were first transformed to standard deviation scores (SDS) using the Dutch Child Growth Foundation’s growth reference program (Growth Analyzer 2.0 SP2, version 2.2) to adjust for age and sex. For example, an SDS of 0 means that the measurement of the individual is equal to the mean of the reference population of the same age and sex. We calculated the difference between the SDS at the start of the study and the SDS after 2 years of follow-up for each child. The sample size of 100 in each group had 90% power to detect a difference of 0.18 SDS (SD, 0.40) with a 2-sided significance level of .05. Two expert pediatric endocrinologists considered a difference of 0.25 SDS to be clinically relevant.

The sample size of 50 boys in each group had 90% power to detect a probability of 0.68 that a measurement of testicular volume in the pravastatin group is less than an observation in the placebo group with a 2-sided significance level of .05. The pediatric endocrinologists considered a probability of 0.7 to be clinically relevant. The power for other safety outcomes was not calculated.

Statistical Analyses
At baseline, mean values between the treatment groups were compared using a t test; data with a skewed distribution were first log-transformed. χ² Tests were applied for comparing distributions of dichotomous data between the groups. Differences in IMT between the treatment groups in terms of change from baseline after 2 years were analyzed with analysis of covariance (ANCOVA), in which the independent variables were treatment group and baseline IMT. In addition, several multivariate models were built to explore the effects of age, sex, and interaction terms. In some cases, more than 1 child per family was included, and consequently, data were related to a small extent. Therefore, data were also analyzed with linear regression analysis adjusted for family number using generalized estimating equations in the GENMOD procedure of SAS. Treatment differences in change from baseline after 2 years in terms of lipids, lipoproteins, and safety measurements (hormones, liver and muscle enzymes, height, weight, and menarche or testicular volume) were analyzed with ANCOVA, with adjustments made for baseline values. Data with a skewed distribution were first log-transformed. Occurrences of moderate elevations of AST, ALT, and CPK during 2 years of treatment were compared by using the Fisher exact test. Furthermore, mixed-model analysis of variance with (linear) time and treatment effects and their interactions were used.
to assess the rates of change in AST, ALT, and CPK during follow-up.

Analyses were interpreted at the 2-sided significance level of .05. Statistical analyses were computed with SAS software, version 8.02 (SAS Institute Inc., Cary, NC).

RESULTS

Characteristics of Children

In total, 274 consecutive statin-naive children whose initial LDL-C levels were at least 155 mg/dL were evaluated (Figure 1). In 44 cases, parents, child, or both declined participation, and in 9 children, the second LDL-C level was below 155 mg/dL. Seven children were excluded for homozygous familial hypercholesterolemia (n = 3), hypothyroidism (n = 1), hypertriglyceridemia (n = 1), or persistently elevated levels of muscle or liver enzymes (n = 2).

Thus, 214 children (100 boys and 114 girls) were randomized, 106 to pravastatin and 108 to placebo (Figure 1). The mean and median age was 13.0 years (range, 8.0-18.5 years). In 205 children (96%), the diagnosis of familial hypercholesterolemia was confirmed by characterization of the mutation in the LDL receptor gene. Baseline characteristics were similar in the 2 groups with respect to age, smoking frequency, systolic and diastolic blood pressure, sex distribution, and, in girls, menarche (Table 1). Premature cardiovascular disease was present in 34% of the affected parents (median age, 37 [range, 20-50] years), while 10% of parents with familial hypercholesterolemia had already died of cardiovascular disease (median age, 37 [range, 23-45] years).

Ten children (all girls; 5 in the pravastatin and 5 in the placebo group) discontinued the study prematurely because they withdrew consent. However, only 3 of them had no 2-year follow-up data (2 children in the pravastatin group and 1 in the placebo group). The available lipids, IMT, and safety data were included in the primary efficacy and safety analyses as collected until discontinuation. At 18 months of treatment, both groups were compliant with their diets, with better fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fat intake than found in the survey of habits22 and slightly worse fa

Abbreviations: HDL, high-density lipoprotein; IMT, intima-media thickness; LDL, low-density lipoprotein.

SI Conversions: To convert cholesterol values to mmol/L, divide by 38.67; to convert triglyceride values to mmol/L, divide by 88.57.

*Data are expressed as mean (SD) except triglycerides and lipoprotein(a), expressed as median (interquartile range).

†P values apply to the difference in change from baseline between the 2 groups.

‡Mean carotid IMT was calculated as the means of common carotid artery, carotid bulb, and internal carotid artery.
between the 2 groups became statistically significant (P value changed from .06 to .04). The difference in the changes in the mean combined carotid IMT became statistically slightly more pronounced (P value changed from .02 to .01).

**Lipid and Lipoprotein Levels**

As expected, pravastatin significantly reduced mean LDL-C levels compared with placebo (−24.1% vs +0.3%; P<.001; absolute differences are shown in Table 2), which was maintained over the 2-year study period. High-density lipoprotein cholesterol, triglyceride, and lipoprotein(a) levels did not change significantly in pravastatin-treated children.

**Safety and Tolerability**

Compliance with study medication, as assessed by tablet counting, revealed that 84% of tablets were taken, whereas the mean visit attendance per child was 95% of all study visits.

At baseline, the education level in the 2 groups was equal (P=.68). During the 2-year treatment, pravastatin had no effect on academic performance; in both groups, 11 children had to repeat a school year once.

The height of the children increased similarly in the pravastatin and the placebo groups (7.9 [5.7] and 7.8 [6.1] cm, respectively). Weight increased 8.0 (5.8) kg in the pravastatin group and 7.8 (5.5) kg in the placebo group. Therefore, body mass index increased 1.3 (1.6) in the pravastatin group and 1.2 (1.3) in the placebo group. During the trial, 5 girls in the placebo group started menses at a mean age of 12.3 (1.3) years, whereas 12 girls in the pravastatin group started menses at a mean age of 12.4 (1.8) years. At the end of the trial, in both groups, 42 of 57 girls were postmenarchal. During the 2 years of follow-up, changes in testicular volume and Tanner staging scores were not different between the groups (Table 3 and Table 4).

All endocrine function parameters at entry and after 2 years were not significantly different between the pravastatin and placebo groups (Table 3). At the end of the trial, no relevant differences were observed with respect to changes from baseline.

**Data are expressed as median (interquartile range) because of skewed distribution.
baseline for AST, ALT, or CPK (Table 3). No higher than 3-fold elevation occurred in ALT and elevation of higher than 3-fold AST levels occurred only twice in the placebo group. A higher than 4-fold elevation in CPK occurred 4 times in the pravastatin group and 3 times in the placebo group. There was no difference between the 2 groups with respect to the rate of change of AST, ALT, or CPK during follow-up. One child had an asymptomatic but extreme CPK elevation (16,400 U/L) after 168 days of study therapy. Within 1 week after stopping the study regimen, her CPK level decreased to normal levels. The study regimen was reinstated, and at the end of the trial, the child was found to have been allocated to placebo.

**COMMENT**

In this randomized, double-blind, placebo-controlled study, we assessed the 2-year efficacy and safety of pravastatin therapy in children with familial hypercholesterolemia. We were able to show that statin treatment improved the lipoprotein profile toward more physiological levels and we observed regression of carotid IMT. This shows that the increased arterial wall thickness progression found in children with familial hypercholesterolemia is reversible. Moreover, we extensively analyzed possible adverse events and untoward influences on growth and maturation of the children and none were observed, although some of our safety outcomes may have been underpowered. Finally, the long-term tolerability of pravastatin was excellent in these children. Discontinuation of the study protocol was a rare event and equally distributed between the active medication and placebo groups. So far, only a few studies have evaluated statin treatment in children with familial hypercholesterolemia. These studies showed promising short-term efficacy and reassuring safety in terms of changes in hepatic and muscle enzymes. Our results are based on longer follow-up and broader safety measurements. While a previous study using simvastatin did show mild changes with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibition, our study showed that levels of dehydroepiandrosterone sulfate and cortisol were unchanged after 2 years of pravastatin therapy.

Several methodological aspects of our study require comment. Carotid IMT progression in the placebo group was less than expected, possibly as a consequence of strict adherence to a healthy lifestyle, including a strict diet, frequent physical activity, and a low frequency of cigarette smoking. Also, we used only a surrogate marker of future vascular disease and could not assess clinical end points, but solid evidence exists that changes in arterial wall IMT are predictive of cardiovascular outcome. To limit IMT measurement variability, a single ultrasound machine was used, 1 experienced sonographer performed all ultrasonography, and images were analyzed by a single reader. To reduce variability further, image analysis software automatically investigated each IMT measurement and accounted for the video line interpolation of the ultrasound equipment. In addition, the double-blind design ensured that all study personnel were unaware of treatment allocation. Nevertheless, our findings cannot be extrapolated to children with an increased atherosclerotic risk as a result of disorders other than familial hypercholesterolemia. In children with familial hypercholesterolemia, IMT likely constitutes a strong marker of future risk because it is part of the pathophysiological pathway from severe hypercholesterolemia to endothelial dysfunction, early atherosclerosis, and premature onset of cardiovascular disease. Our IMT findings and the observed efficacy of pravastatin treatment should therefore be restricted to children with familial hypercholesterolemia.

Although this trial in children with familial hypercholesterolemia has, to our knowledge, the most extensive follow-up to date, data on even longer-term safety and efficacy of statin therapy in children are needed.

Study concept and design: Wiegman, de Groot, Bakker, Sijbrands, Kastelein. Acquisition of data: Wiegman, de Groot. Analysis and interpretation of data: Wiegman, Hutten, de Groot, Rodenburg, Büller, Sijbrands, Kastelein. Drafting of the manuscript: Wiegman, Hutten, Sijbrands. Critical revision of the manuscript for important intellectual content: Wiegman, Hutten, de Groot, Rodenburg, Bakker, Büller, Sijbrands, Kastelein. Statistical expertise: Hutten, de Groot, Sijbrands. Obtained funding: Bakker, Kastelein. Administrative, technical, or material support: Rodenburg. Supervision: Bakker, Sijbrands, Kastelein.

**Funding/Support:** We would like to thank Zorg Onderzoek Nederland (Prevention Fund of the Dutch Government) for initial financial support of this study (grant 28-2572). Dr Kastelein is an established investigator of the Netherlands Heart Foundation (grant 2000D039). This work was supported in part by an unrestricted grant from Bristol-Myers Squibb Inc, Princeton, NJ.

**Role of the Sponsors:** The sponsor had no role in the design and conduct of the study, in the collection, analysis, and interpretation of the data, or in the preparation, review, or approval of the manuscript.

**Acknowledgment:** We thank Tom Vulsma, MD, PhD, and Paul S. A. van Trotsenburg, MD, pediatric endocrinologists, for their expertise in safety parameters.
