Effect on the Quality of Peer Review of Blinding Reviewers and Asking Them to Sign Their Reports

A Randomized Controlled Trial

Fiona Godlee, BSc, MRCP; Catharine R. Gale, BSc; Christopher N. Martyn, DPhil, FRCP

Context.—Anxiety about bias, lack of accountability, and poor quality of peer review has led to questions about the imbalance in anonymity between reviewers and authors.

Objective.—To evaluate the effect on the quality of peer review of blinding reviewers to the authors’ identities and requiring reviewers to sign their reports.

Design.—Randomized controlled trial.

Setting.—A general medical journal.

Participants.—A total of 420 reviewers from the journal’s database.

Intervention.—We modified a paper accepted for publication introducing 8 areas of weakness. Reviewers were randomly allocated to 5 groups. Groups 1 and 2 received manuscripts from which the authors’ names and affiliations had been removed, while groups 3 and 4 were aware of the authors’ identities. Groups 1 and 3 were asked to sign their reports, while groups 2 and 4 were asked to return their reports unsigned. The fifth group was sent the paper in the usual manner of the journal, with authors’ identities revealed and a request to comment anonymously.

Main Outcome Measure.—The number of weaknesses in the paper that were commented on by the reviewers.

Results.—Reports were received from 221 reviewers (53%). The mean number of weaknesses commented on was 2 (1.7, 2.1, 1.8, and 1.9 for groups 1, 2, 3, and 4 and 5 combined, respectively). There were no statistically significant differences between groups in their performance. Reviewers who were blinded to authors’ identities were less likely to recommend rejection than those who were aware of the authors’ identities (odds ratio, 0.5; 95% confidence interval, 0.3-1.0).

Conclusions.—Neither blinding reviewers to the authors and origin of the paper nor requiring them to sign their reports had any effect on rate of detection of errors. Such measures are unlikely to improve the quality of peer review reports.

RESULTS

Of the 420 reviewers invited to comment on the manuscript, 221 (53%) turned a report. Among the 74 people (18%) who gave a reason for declining to review the manuscript, 46 said they felt they were not competent to comment and 16 said they were too busy. There were no statistically significant differences in response rate among the 5 groups of reviewers. The 5 groups did not differ significantly by demographic or academic characteristic. Those who reported on the manuscript tended to have reviewed for more journals in the previous year than the nonresponders. They were also more likely to be on the editorial board of a biomedical journal and to have received a higher grading for their past performance in writing reports by BMJ. Characteristics of respondents and nonrespondents are shown in Table 1.

In total, 8 areas of weakness in design, analysis, or interpretation had been introduced into the manuscript. The mean number of weaknesses commented on was 2. Only 10% of reviewers identified 4 or more areas of weakness, and 16% failed to identify any.

We found no statistically significant difference in performance among the 37 reviewers in group 5 who had been sent the manuscript under the same conditions as groups 1 and 3. Reviewers in group 4 who had been sent the manuscript in the usual manner of BMJ and were unaware that they were taking part in a study and the 35 reviewers in group 5 who had been sent the manuscript under the same conditions but informed that they were participating in a study. These groups were therefore compared when we examined whether blinding reviewers and/or asking them to sign their reports affected the proportion of weaknesses they identified. Table 2 shows the mean number of errors detected by each group and rate ratios for identifying weaknesses. There were no statistically significant differences. Among the 90 respondents who had been blinded to the authors’ identities, 23 (26%) named the authors correctly in their report. Rate ratios were little changed when these people were excluded.

We also examined whether other characteristics of the reviewers were linked with better performance at identifying weaknesses in the manuscript (Table 3). Reviewers who had postgraduate training in epidemiology or statistics tended to comment on more points of weakness, but this relationship was not statistically significant. Neither sex nor experience as a peer reviewer or as a member of an editorial board was associated with the quality of the report. Younger reviewers, those currently involved in biomedical research, those with more publications in the previous 5 years, and those who had received a higher grad-

knowing for their past performance in writing reports by *BMJ* were all more likely to identify weaknesses in the manuscript. In multivariate analysis, *BMJ* grade and number of publications remained statistically significant predictors of the number of errors detected.

Despite the weaknesses of the manuscript, 78 reviewers (33%) recommended that it be published with minor revision. Twenty-seven reviewers (12%) recommended that the manuscript should be published with major revision and 66 (30%) advised that it be rejected. Fifty-five (25%) made no recommendations regarding publication.

Reviewers in groups 1 to 4 who were aware they were taking part in a study tended to recommend outright rejection of the manuscript more often than those in group 5 who were unaware that they were participating in a study. We calculated odds ratios (ORs) for recommending rejection according to whether the reviewers had been blinded to the authors’ identities or asked to sign their reports, restricting the analysis to groups 1 to 4. Reviewers who had been blinded were less likely to recommend rejection than those who were not blinded (OR, 0.5; 95% confidence interval [CI], 0.3-1.0). This association was strengthened when reviewers who identified the authors’ correctly were excluded (OR, 0.3; 95% CI, 0.1-0.6). Those who were asked to sign their reports were slightly less likely to recommend rejection than anonymous reviewers, but this relation was not statistically significant (OR, 0.7; 95% CI, 0.3-1.4).

**COMMENT**

This randomized controlled trial was designed to investigate the effects of blinding reviewers to the authors’ identities and asking them to sign their reports in a context as close as possible to the usual way in which *BMJ* operates peer review. We found that these interventions had no effect on the quality of reviewers’ reports as judged by the number of weaknesses that they identified in the manuscript. Although 4 of the 5 groups of reviewers knew that they were taking part in a study, their performance in detecting errors did not differ from those of the fifth group who were unaware that they were participating. We do not think that knowledge that they were taking part in the study is likely to have influenced these results. However, the response rate in the study was lower than usual for *BMJ* reviewers. Part of the explanation may be that the expertise of some of the reviewers we approached may have been peripheral to the subject of the manuscript. We know that 46 potential reviewers declined to write a report because they felt unqualified to comment. This point should also be borne in mind when considering the quality of the reports. Similar findings on reviewers’ shortcomings at detecting weaknesses in a manuscript have been reported previously. While a reviewer who discovered 4 or 5 serious flaws in a manuscript might reasonably feel that it was unnecessary to mention more, this can hardly explain the low mean score. Had we chosen reviewers with more relevant expertise, the score might have been higher.

The questionnaire allowed us to investigate which characteristics of reviewers were associated with the most complete detection of errors in a manuscript. As others have shown, younger reviewers performed better than older reviewers. We also found, perhaps unsurprisingly, that reviewers who had themselves published a large number of articles in the past few years tended to identify more errors than those who had published little and that reviewers whose past performance in reviewing for *BMJ* had been highly rated by the editorial staff also tended to perform better.

One intriguing finding concerns reviewers’ recommendations to the editor about publication. The groups who were blind to authors’ identities were the least likely to recommend rejection.

Blinding reviewers to the identities and affiliations of authors and requiring them to sign their reports might prove to be a successful strategy in reducing bias and increasing accountability in peer review, though it is hard to ensure that blinding is complete. It may also make them less likely to recommend rejection. But the results of this study do not suggest that such measures would be very effective in improving the accuracy with which they detect weaknesses in a manuscript.

We are grateful to members of Locknet (the international peer review research network), Richard Smith, BSc, MB, ChB, and Margaret Benfell of *BMJ*, and Paul Winter, MSc, of the MRC Environmental Epidemiology Unit for advice and assistance.

Does Masking Author Identity Improve Peer Review Quality?
A Randomized Controlled Trial

Amy C. Justice, MD, PhD; Mildred K. Cho, PhD; Margaret A. Winker, MD; Jesse A. Berlin, ScD; Drummond Rennie, MD; and the PEER Investigators

Context.—All authors may not be equal in the eyes of reviewers. Specifically, well-known authors may receive less objective (poorer quality) reviews. One study at a single journal found a small improvement in review quality when reviewers were masked to author identity.

Objectives.—To determine whether masking reviewers to author identity is generally associated with higher quality of review at biomedical journals, and to determine the success of routine masking techniques.

Design and Setting.—A randomized controlled trial performed on external reviews of manuscripts submitted to Annals of Emergency Medicine, Annals of Internal Medicine, JAMA, Obstetrics & Gynecology, and Ophthalmology.

Interventions.—Two peers reviewed each manuscript. In one study arm, both peer reviewers received the manuscript according to usual masking practice. In the other arm, one reviewer was randomized to receive a manuscript with author identity masked, and the other reviewer received an unmasked manuscript.

Main Outcome Measure.—Review quality on a 5-point Likert scale as judged by manuscript author and editor. A difference of 0.5 or greater was considered important.

Results.—A total of 118 manuscripts were randomized, 26 to usual practice and 92 to intervention. In the intervention arm, editor quality assessment was complete for 77 (84%) of 92 manuscripts. Author quality assessment was complete on 40 (54%) of 74 manuscripts. Authors and editors perceived no significant difference in quality between masked (mean difference, −0.1; 95% confidence interval [CI], −0.2 to 0.4) and unmasked (mean difference, −0.1; 95% CI, −0.5 to 0.4) reviews. We also found no difference in the degree to which the review influenced the editorial decision (mean difference, −0.1; 95% CI, −0.3 to 0.3). Masking was often unsuccessful (overall, 68% successfully masked; 95% CI, 58%-77%), although 1 journal had significantly better masking success than others (90% successfully masked; 95% CI, 73%-98%). Manuscripts by generally known authors were less likely to be successfully masked (odds ratio, 0.3; 95% CI, 0.1-0.8). When analysis was restricted to manuscripts that were successfully masked, review quality as assessed by editors and authors still did not differ.

Conclusions.—Masking reviewers to author identity as commonly practiced does not improve quality of reviews. Since manuscripts of well-known authors are more difficult to mask, and those manuscripts may be more likely to benefit from masking, the inability to mask reviewers to the identity of well-known authors may have contributed to the lack of effect.
